## Self-Assessment 3

### Signal Data Science

We'll be having another self-assessment. As before,

- Type your answers in a new R script file with comments indicating where the answer to each question begins.
- Write down your starting time. When you finish, mail signaldatascience@gmail.com with your R script attached along with the amount of time you spent on the self assessment.
- Work individually. You can however consult R documentation, look at old assignments, use the Internet, etc., but don't copy and paste code verbatim.
- Make your code as clear, compact, and efficient as possible. Use everything
  that you've learned! Please comment and organize your code so we can
  easily tell how parts of your R script correspond to specific problems.

Packages you may find useful: ggplot2.

# **Part 1: Probability**

In Part 1, we'll look at computational approaches to a variety of probability-based interview questions.

#### Hashmap collisions

From "120 Interview Questions", we have the following:

Your hash function assigns each object to a number between 1:10, each with equal probability. With 10 objects, what is the probability of a hash collision? What is the expected number of hash collisions? What is the expected number of hashes that are unused?

Use sample(..., replace=TRUE) to give estimates of all three.

(*Clarification*: If n objects are assigned to the same hash, that counts as n-1 hash collisions.)

### Rolling the dice

Here's a nice question from one of the first cohort's students:

Given a fair, 6-sided dice, what's the *expected number of rolls* you have to make before each number (1, 2, ..., 6) shows up at least once?

Write code to estimate the answer.

#### **Bobo the Amoeba**

Here's a problem commonly found in quantitative finance interviews, an easier version of which sometimes appears in data science interviews:

Bobo the amoeba can divide into 0, 1, 2, or 3 amoebas with equal probability. (Dividing into 0 means that Bobo dies.) Each of Bobo's descendants have the same probabilities. What's the probability that Bobo's lineage eventually dies out?

I'll outline a computational path for you to estimate the solution to this problem. In particular, we're going to simulate a large number of amoeba lineages over time to determine how the probability of total extinction changes as we iterate forward in time.

- Write a function next\_gen(n) that takes in an initial number of amoebas n, determines how many amoebas are in the next generation according to the probability above, and returns that value. Sanity check: next\_gen(1) should return 0, 1, 2, or 3 with equal probability.
- Note the enormous computation time required for next\_gen(n) when n is very large. If there are a *large* of amoebas, we can assume (with reasonable confidence) that the lineage isn't going to die out. Pick a reasonably large value of n, like 500 let's call it N and modify next\_gen(n) to just return N+1 when n > N. (This is fine because we just want to know if the lineage will *die out* or not how huge the population can get in cases where it doesn't don't really matter to us.)
- We're going to simulate num\_lineages lineages for n\_gens generations, so set num\_lineages = 10000 and n\_gens = 30.
- Initialize a matrix of appropriate size and dimensions, where each column represents a single lineage of amoebas and every row represents a different generation. Next, set the initial generation to a population of 1.
- Iterate over the number of generations. For each iteration, apply next\_gen(n) to the population of the most recent generation to get the population for the next generation, filling in the values of your population matrix.

- Turn your population matrix into a matrix of 1s and 0s corresponding to whether the lineage was still alive or died out at each step of the simulation.
- Calculate the probabilities of lineage extinction from your population matrix. *Hint:* Take the rowSums() of the matrix.
- qplot() the time evolution of the extinction probability. What do you think it is? Give a numerical estimate using your calculations.

Now, use WolframAlpha to solve the cubic equation  $p = \frac{1}{4} + \frac{1}{4}p + \frac{1}{4}p^2 + \frac{1}{4}p^3$ . One of the solutions will numerically correspond to your calculated probability. Which one? Why?
